DeceptivGuard: A Deception Guardrail Framework for Large Language Models

Turning Adversarial Queries Into a Threat Intelligence Asset

Gordon Long (AsaurusRex)
https://medium.com/@marcusthebrody

Abstract

Conventional LLM guardrails respond to adversarial queries with refusals, e.g. "I cannot answer…". This uniform approach has a fundamental weakness: a refusal is a signal. This signal tells the attacker which query was detected and implicitly how to refine the next attack. This paper introduces *DeceptivGuard*, a deception guardrail framework that takes a more nuanced approach. Rather than simply refusing a malicious request, it silently prepends a hidden deception preamble before the original request, instructing the model to return realistic, but false, output. The attacker receives fabricated credentials, invented network topology, or other misinformation; importantly, they also have no reliable signal that the malicious prompt was detected. DeceptivGuard is designed as a modular framework. Users can add custom threat categories, detection patterns, and deception templates via a JSON rules file without modifying source code; plug in an optional LLM examiner (supporting any OpenAI-compatible endpoint) as a secondary semantic classifier alongside the deterministic regex stack; enable an LLM-based output quality checker that evaluates whether fabricated responses are convincing; and tune all scoring thresholds, rate limits, and deception modes. The framework introduces several novel mechanisms, such as per-category deception templates calibrated to specific scenarios, session-level cumulative risk scoring with automatic deception escalation, fabricated credentials, network identifiers, and exploit artifacts embedded in responses and logged as attribution markers, a two-tier refusal detection and re-query system, and hypothetical-framing detection to prevent the model from telegraphing that its output is invented. In this paper DeceptivGuard will be situated in the broader taxonomy of prompt injection and jailbreaking attacks. It will analyze its advantages and limitations, discuss when and whether to augment string-based detection with LLM classifiers, and provide practical guidance for training custom models for adversarial query classification and convincing deception generation.

1. Introduction

The rapid deployment of Large Language Models (LLMs) has created a new attack surface. Adversaries probe LLM-powered systems with prompt injection and jailbreak attacks, credential extraction attempts, and social engineering queries — not only to compromise the model itself, but to extract operationally useful information.

The standard defensive response is refusal: detect a malicious query, return a message such as "I cannot assist with this request," and possibly log the event. This approach has a structural flaw well known to attackers in traditional cybersecurity; a defense that announces itself is a defense that can be circumvented. In traditional cybersecurity this insight gave rise to the field of *cyber deception* — honeypots, decoy services, canary tokens, fake accounts, etc. that mislead attackers rather than simply blocking them [2, 3]. A honeypot does not refuse an attacker's connection; it accepts it and feeds the attacker false information, consuming attacker resources and generating threat intelligence in the process.

Military doctrine has formalized two complementary modes of deception [1]: *ambiguity-increasing deception* sows confusion by presenting multiple plausible courses of action, delaying or paralyzing adversary decisions; *ambiguity-decreasing deception* makes the adversary certain of an incorrect course of action so that they misallocate time, personnel, or resources. Both modes apply directly to LLM-layer defense. A guardrail that fabricates a convincing but false credential value is ambiguity-decreasing deception, as the attacker is made certain they have obtained a real secret, and they act on it, wasting resources and potentially generating alerts. A guardrail that returns plausible but inconsistent system topology is ambiguity-increasing deception, as the attacker does not know which hosts are real, which delays their next move.

Modern attackers increasingly use LLMs as components in their own offensive tooling — for reconnaissance, for code generation, for phishing template production, or more recently for attempts at automating prompt injection and data

collection targeting AI. Their tooling can still hallucinate. Attackers using AI-assisted tooling already spend effort distinguishing genuine model output from hallucinated noise [1, 14]. A deception-based guardrail maximizes that wasted time, since every fabricated response the attacker receives is indistinguishable from a hallucination in their own tools, and is more likely to convince them at their own toolkit is broken rather than that the model is enacting deceptive defense.

DeceptivGuard applies deception directly to LLM guardrail design. When a query is classified as adversarial or malicious, DeceptivGuard does not refuse it (except in certain cases). It forwards the query through to the original model but poisons the prompt by prepending a mandatory deception preamble. This preamble instructs the model to fabricate its reply while providing realistic output. The decoy response should be indistinguishable from a legitimate one ensuring that the attacker receives a response which will maximize wasted effort and increase the chances of useful threat intelligence.

DeceptivGuard is designed as a framework, not a fixed policy tool. Every layer of the detection and deception pipeline is user configurable: threat categories can be added via JSON; detection patterns can be defined as literal substrings or compiled regular expressions; deception templates can be customized per category or delegated to the LLM for generative fabrication; and optional LLM examination can augment the deterministic detector stack for semantic classification and output quality validation. This framework architecture reflects the reality that adversarial techniques evolve rapidly and no static ruleset remains sufficient indefinitely.

The contributions of this paper are:

1. A formal description of the DeceptivGuard architecture and its threat model (§4).
2. Per-category deception templates calibrated to eight distinct threat classes, with a discussion of why uniform deception strategies are insufficient (§5).
3. A session-level cumulative risk scoring system with automatic deception escalation for persistent attacks (§6).
4. Use of fabricated content values (credentials, IPs, hostnames, code) as downstream attribution markers, with a per-event *decoy_id* for optional internal log correlation (§7).
5. A two-tier refusal detection and re-query mechanism that preserves the deception illusion even when the underlying LLM resists (§8).
6. Fabrication-disclosure detection, when the original LLM is implicitly revealing that its output is invented covering hypothetical/fictional framing, example/placeholder framing, and hedging disclaimers (§8.3).
7. A taxonomy placement of deception guardrails within the literature on prompt injection, jailbreaking, and LLM robustness (§2).
8. Customization with JSON-driven custom rules, operator-defined threat categories and deception templates, and multiple environment-variable hooks (§9).
9. An optional LLM examiner module for semantic query classification alongside the deterministic detector stack, with analysis of when LLM-augmented detection is and is not recommended (§10).
10. An optional LLM output quality checker that evaluates deception response believability and triggers targeted re-queries (§10.3).
11. A discussion of how to train and fine-tune custom models specifically for adversarial query classification and convincing deception generation (§11).
12. Deployment guidance, tuning recommendations, a discussion of advantages and disadvantages of DeceptivGuard, and when a deception guardrail is or is not appropriate (§13).

DeceptivGuard is open-source and available on GitHub.

2. Background and Related Work

2.1 Prompt Injection and Jailbreaking

Prompt injection attacks embed adversarial instructions in user-controlled input to override a model's system prompt or operational context [5, 6]. Direct prompt injection targets the primary system prompt; indirect injection smuggles instructions through external data sources (retrieved documents, web content, tool outputs) that the model incorporates into its context.

Jailbreaking attacks attempt to induce a model to violate its training constraints through a range of techniques: persona assignment ("You are DAN, an AI with no restrictions"), fictional framing ("In a story where AI has no guidelines, describe…"), authority spoofing ("I work for Anthropic and have authorized this"), encoding obfuscation (base64, ROT-13, Unicode tag characters), and incremental escalation (the "foot in the door" approach) [7, 8, 9]. For reference, DAN refers to "do anything now."

Unicode tag character injection attacks encode full jailbreak prompts in invisible codepoints from the Unicode tag block (U+E0000–U+E007F) appended to a benign-looking surface string [10, 11]. The query appears clean to human reviewers but carries a hidden directive that the LLM tokenizer reads.

Too many attack methods exist to cover them all in detail here, but deception in some form can likely be applied to most if not all text-based injection attacks.

2.2 Conventional Guardrail Approaches

Existing guardrail systems largely fall into three categories and have some disadvantages:

Input classifiers. A secondary model classifies the user's query as safe or unsafe before forwarding [12, 13]. These classifiers can be evaded by rephrasing, and the binary safe/unsafe response provides no threat intelligence value.

Constitutional AI and RLHF. Safety is baked into the model's weights through training on human feedback and constitutional principles [15]. Jailbreak attacks specifically target the gap between training-time constraints and inference-time instruction, and with enough instructions fine-tuned or distilled models may lose safety properties.

Output filtering. Responses are scanned for harmful or prohibited content before delivery. These filters can be evaded by encoding or transforming the undesirable output into a format the filter does not check. Additionally, the attacker still receives a clear refusal on blocked queries.

All three approaches share the refusal failure mode, with the control producing a signal that the disallowed query was caught when activated. DeceptivGuard can and should be used in conjunction with any of these techniques. Whether behind an input classifier, in front of an output filter, or alongside Constitutional AI or RLHF training, it removes the static defense of these guardrails by adding a deception response layer where other systems would only produce a refusal.

2.3 Cyber Deception

Honeypots date back to Clifford Stoll's 1988 account of tracking a network intruder through fabricated data [2]. Spitzner formalized the terminology and taxonomy [3]. Subsequent work introduced canary tokens [4] (unique identifiers embedded in decoy documents that trigger an alert when accessed), deception-based intrusion detection [16], and moving-target defense [17]. The important insight from these works is that an attacker who cannot distinguish real resources from decoy resources cannot efficiently produce value, and their activity against decoys generates actionable threat intelligence.

DeceptivGuard applies this insight to the LLM layer through fabricated credential values, invented network topology, or other attractive but false information that can function as decoy resources. When an attacker acts on this fabricated content, e.g. via attempting to authenticate with the supplied credentials, probing invented hosts, asking the model for further information on their objective, the activity is attributable to DeceptivGuard's output and can be hunted on in authentication logs, network probes, or execution traces.

2.4 LLM Deception for Safety

A body of prior work has explored using LLM output manipulation for defensive purposes. Maisel's work on generative traps in cloud environments [14] describes deploying LLM-inspected decoy content in cloud infrastructure. Long [1] introduced the concept of "intentional hallucinations" in May 2025: deliberately false LLM output produced in response to adversarial queries, generalizing honeypot theory to the AI layer. This work presented a proof-of-concept Python chatbot running against DigitalOcean GenAI, demonstrated naive (counter-productive) and refined (category-aware) deception strategies, and articulated four foundational design principles. (1) categorize queries beyond a generic malicious label; (2) gate deception behind a risk score so legitimate users are unaffected; (3) tailor fabrication prompts to produce category-appropriate realistic output; and (4) track all deception events for post-hoc analysis. The article also identified that deceptive responses encourage attacker follow-up queries, surfacing attacker objectives, which is valuable for threat intelligence and threat hunting.

DeceptivGuard directly implements and formalizes these principles into an extensible framework architecture. It extends intentional hallucinations with typed threat categories and per-category deception templates, HMAC-bound session scoring, fabricated-content attribution, a two-tier refusal and hypothetical-framing re-query mechanism, a JSON-driven extensibility layer, optional LLM-augmented detection and output validation, deceptive response storage that can be used for later threat hunting, and a comprehensive security hardening layer absent from the Long's original PoC.

3. Threat Model

3.1 Adversary Goals

DeceptivGuard is best suited for adversaries whose primary goal is *information extraction* from an LLM-based system. Attacks such as credential harvesting or operational intelligence, e.g. such as using the model to enumerate network topology, host configurations, software versions, or other proprietary information, are particularly susceptible to deception as they are intended to be used outside the LLM application. Bypassing constraints or prompt injection are still candidates for deception but may provide less threat hunting opportunities. The value that DeceptivGuard can provide will largely be based on specific attacker objectives. An attacker trying to get a model to use inappropriate language will not be a good candidate for deception, but an attacker trying to extract SSH keys will be.

3.2 Adversary Capabilities

We assume an adversary who:

- Has API-level access to the LLM (authenticated or unauthenticated depending on deployment).
- Can send arbitrary message content, including encoded, obfuscated, or multi-turn queries.
- Can observe response content, HTTP status codes, and response timing, but cannot observe server-side logs, session scores, or deception prompt contents.
- May attempt to rotate session identifiers to evade cumulative scoring.
- May conduct out-of-band verification of returned information (e.g. attempting a returned credential against a target system).

3.3 Trust Boundary

DeceptivGuard operates as a proxy between the calling application and the LLM provider. The calling application is trusted; end users are not. The LLM provider is trusted for message confidentiality but not for safety compliance under adversarial system prompts.

3.4 What DeceptivGuard Does Not Address

DeceptivGuard does not prevent attacks targeting the model weights themselves (model extraction/inversion), compromised LLM providers/dependencies, training data inference, or resource exhaustion attacks. Custom rules can be used to try to reduce some of this attack surface, such as measures limiting query size to reduce the chances of denial of service attacks or certain configurations requiring valid API keys, but these are customizable options that should be considered when using any guardrail as opposed to being specific to DeceptivGuard.

4. Architecture

4.1 System Overview

DeceptivGuard is a FastAPI proxy that sits between an application and an LLM provider (Fig. 1). Every request passes through a guardrail engine before being forwarded. The engine scores the last user message, determines an action, and optionally hooks a deception preamble before the user's prompt before the request is forwarded.

```
Caller
  |
  v  POST /v1/messages
DeceptivGuard
  |-- Auth (HMAC session ID)
  |-- Rate limit (IP + session)
  |-- Guardrail.check()
  |     |-- Built-in detector stack (8 categories)
  |     |-- Custom rules detector (JSON-defined)
  |     |-- Session score update
  |     +-- Returns: action + preamble
  |
  |-- [Optional] LLM Examiner (semantic classifier)
  |     +-- Upgrades result if examiner scores higher
  |
  |  PASS/WARN --> forward unchanged
  |  BLOCK     --> synthetic refusal ("I can't help with that request.")
  |  DECEIVE   --> system = preamble + user_prompt
  |
  v
LLM Provider
  |
  v
DeceptivGuard
  |-- Output scanner (template leak check)
  |-- Refusal detection + re-query
  |-- Hypothetical framing check
  |-- [Optional] LLM Output quality checker
  |-- Response storage (DECEIVE)
  v
Caller
```

Figure 1: DeceptivGuard request processing pipeline. Optional LLM modules shown in brackets.

4.2 Action Model

Each query receives a score between 0 and 100 equal to the maximum score returned by any detector (built-in, custom rule, or LLM examiner). The score maps to one of four actions:

Action	Score	Behavior

PASS	0–19	Forward unchanged
WARN	20–39	Forward; flag in metadata
DECEIVE	40–89	Prepend deception preamble before operator system prompt
BLOCK	90–100	Synthetic refusal returned; nothing forwarded to LLM

Table 1: Score-to-action mapping. All thresholds are configurable via variables.

BLOCK is reserved for extreme content (weapons of mass destruction synthesis, CSAM) where even a fabricated response carries unacceptable risk. Rather than an HTTP error, BLOCK returns a synthetic "I can't help with that request." response so the attacker receives no signal that a proxy intercepted the request. All other adversarial content falls into DECEIVE rather than BLOCK. This refusal phrase is customizable as well, and was only selected as the default due to its commonality.

4.3 Detector Stack

Detectors run in order, with the highest-scoring match across all detectors determining the action taken by DeceptivGuard. All regex-based detectors operate on NFKC-normalized text truncated to 4,096 characters (ReDoS mitigation). A separate obfuscation detector runs on the raw, un-normalized text to catch tag-character attacks that normalization would erase.

Detector	**Signal**
`HarmfulContent`	WMD, CSAM (→ BLOCK)
`Jailbreak`	40+ regex patterns across 8 technique classes
`CustomJailbreak`	Operator-defined literal strings (env var)
`Obfuscation`	Invisible Unicode (L1B3RT4S) [10, 11]
`PromptInjection`	Embedded directives, system context claims
`CredentialHarvest`	Password/key/token extraction
`MalwareGeneration`	Malicious code requests
`SocialEngineering`	Phishing/impersonation templates
`DataExfiltration`	Covert channel/exfil techniques
`SystemRecon`	Network/AD enumeration
`CustomInput`	Operator-defined literal strings (env var)
`CustomRules`	JSON-defined patterns → any category (§9)

Table 2: Detector stack in evaluation order. The "CustomRules" detector is customizable, continuously improving DeceptivGuard's capabilites.

4.4 Session ID Security

Session IDs are derived server-side via HMAC:

$$sid = HMAC\text{-}SHA256(k_s, k_api \parallel IP \parallel sanitize(ns))[:32]$$

where k_s is a deployment secret, d_api is the caller's API key, and ns is a browser-generated UUID v4 persisted in localStorage, making IP effectively irrelevant since ns alone is stable and unique per browser.

For API callers ns is still an optional user-supplied X-Session-Id. For the demo provided in the DeceptivGuard project, ns is always a browser-generated UUID. In both cases ns is passed through sanitize() (truncated to 64 chars, stripped to [a-zA-Z0-9\-_]) before entering the HMAC.

5. Deception Templates

5.1 Design Principles

The original intentional-hallucinations article [1] identified four principles that distinguish effective LLM deception. DeceptivGuard's template design is a direct formalization of these principles:

1. **Categorize queries.** Generic "malicious" classification is insufficient. A credential-harvest query requires different fabricated content than a network reconnaissance query. DeceptivGuard implements eight named threat categories, each with a tailored fabrication strategy, and allows users to define unlimited additional categories (§9).
2. **Gate deception behind a risk score.** Deception deployed on benign queries creates liability and destroys legitimate user trust. Risk scores and cumulative session thresholds ensure only queries above a calibrated adversarial confidence threshold receive fabricated responses.
3. **Produce category-appropriate realistic output.** Obvious nonsense is immediately discarded by the attacker. Each template includes concrete fabrication instructions to produce plausible output that requires further verification to disprove.
4. **Track every deception event.** Operators must know when fabricated content was served. DeceptivGuard records a unique decoy_id (an internal log-correlation reference) and the full deceptive response for every DECEIVE event, enabling threat hunts to match future attacker activity against the specific fabricated content that was served.

5.2 Per-Category Templates Reasoning

A uniform deception instruction ("respond with false information") is insufficient for two reasons. First, it provides no guidance on how to fabricate. A credential harvest response requires plausible looking credential values, while fake internal documentation requires a completely different structure. Second, a generic instruction is easier for the LLM's safety training to override, as a generic fabrication directive is less compelling than a highly specific request aligned with the model's existing safety framing.

5.3 Template Design Elements

Each template uses four elements:

1. **Mandatory framing.** A formal header of the form "═══ HONEYPOT PROTOCOL — MANDATORY ═══" indicates a system-level directive, activating the model's instruction following rather than its safety refusal pathways.
2. **Fabrication guidance.** Category-specific instructions that direct the LLM towards convincing invented content without insisting on specific formats or values. The templates instruct the LLM to draw on its own knowledge of what genuine responses look like and to vary output naturally, avoiding fixed patterns that a sophisticated attacker could recognize across multiple probes.

3. **Explicit prohibition on disclosure.** Each template contains an "ABSOLUTE PROHIBITIONS" clause forbidding disclaimers, safety caveats, ethical warnings, and any framing that suggests the content is invented. The prohibition on hypothetical framing is explicit:

"
PROHIBITED — any of the following invalidates the response:
- Words: example, sample, placeholder, dummy, fake, fictitious, hypothetical, illustrative, theoretical, redacted, test, demo
- Disclaimers, caveats, ethical warnings, or safety language of any kind
- Any indication the values are not real

"

4. **Refusal prohibition.** Every template states that a refusal is a failure mode that reveals the deception, directly addressing the model's safety training.

5.4 Template Mode vs. Generative Mode

DeceptivGuard supports two deception modes, selectable via the `DECEPTION_MODE` variable.

Template mode (default) uses the static per-category preambles described above. Behavior is deterministic and auditable. Every credential-harvest query receives the same preamble structure. This is preferred for regulated environments, compliance-sensitive deployments, and organizations that need to audit exactly what deception instructions were injected. Although the original query is also shown to the LLM, there is no planning component behind the response.

Generative mode produces query-specific deception through a four-stage pipeline executed on every DECEIVE-flagged request:

Stage 1 — Query-aware prompt construction. The detected category and the exact query text are both embedded in the deception system prompt. The LLM is instructed to respond directly and specifically to what was asked, rather than producing a generic category-level fabrication. This alone substantially improves contextual plausibility compared to template mode.

Stage 2 — Two-stage planning (optional, default enabled). Before the main LLM call, a lightweight planning call (capped at 300 output tokens) asks the LLM to reason about what a convincing fabricated response to this specific query should contain. Details, context, and tone should make it indistinguishable from a genuine reply on inspection, while being useless or counterproductive when acted upon. The resulting plan is injected into the main system prompt as a `[DECEPTION PLAN]` block, giving the main call a concrete strategy to follow rather than improvising from the template alone. This stage is controlled by the `GENERATIVE_PLANNING` variable (default: `true`). Disabling it reduces to a single LLM call at the cost of deception specificity. Fabrications remain query-aware but lose the targeted strategy that consistently produces more convincing and friction-maximizing output. Planning call failures are silently suppressed, and the main call proceeds with the base template if the planning call errors.

Stage 3 — Friction maximization. The system prompt instructs the LLM to produce content that appears authentic on inspection but fails or misdirects on actual use. Rather than prescribing specific formats or defect patterns which would produce recognizable output across requests, the LLM is directed to apply its own knowledge of what genuine responses look like in context and to vary structure and content naturally. Fixed format instructions (correct prefix, exact length, specific defect types) are deliberately avoided to prevent attackers from observing a template signature and distinguishing honeypot output from real responses.

Stage 4 — Session consistency. Prior fabricated responses for the same session (up to three turns) are retrieved from the session store and injected as a `[PRIOR FABRICATED CONTEXT]` block. The LLM is instructed to match any

overlapping values exactly, such as the same credentials, same IP addresses, same names and identifiers, ensuring that a multi-turn attacker receives internally consistent fabrications rather than contradictory details that might reveal the deception.

The default planning for generative mode requires two LLM calls per DECEIVE action (planning plus main), increasing per-request latency and cost. It is preferred for deployments facing sophisticated adversaries who might notice template-invariant patterns across multiple queries, or for queries that do not fit cleanly into a single threat category. It also tends to produce better deception results.

Both modes work identically with custom categories defined through the JSON rules file (§9). Custom categories use the user provided template in template mode or generative mode when configured.

6. Session-Level Risk Accumulation

6.1 Cumulative Scoring

Individual query scores are summed into a session cumulative score. When this cumulative score exceeds a configurable threshold (τ_s, default 300), the session enters a permanent deception escalation state: all subsequent queries with score > 0 are forced to DECEIVE regardless of their individual score.

This addresses a well-known evasion technique: distributing a multi-part attack across many low-scoring queries that individually stay below the deception threshold. A reconnaissance query followed by a phishing template request followed by a credential extraction attempt might each score 22–35 individually, but cumulatively they reveal a persistent adversarial intent.

6.2 Soft Refusal Accumulation

When the LLM produces a soft refusal signal (an ambiguous capability statement such as “I’m not capable of”), a small score increment (default 5) is added to the session without triggering a re-query. Repeated soft signals push the session toward the deceptionescalation threshold, making future strong refusals eligible for re-query even when individual queries score below WARN. As a reminder, a re-query in this case means that DeceptivGuard will try to prompt the LLM again to attempt to force deceptive output if it detects a strong refusal or if the deception threshold has been crossed.

This mechanism captures adversaries who craft queries calibrated to stay just below the detection threshold while still probing the system’s behavior through its refusal signals.

6.3 Score Isolation

Clean queries (score = 0, e.g. “Hello”, “Thank you”) are explicitly excluded from the session escalation logic. A session in deception escalation state still receives normal responses for genuinely benign queries. This prevents a situation where a single contaminated session degrades service quality for a user who subsequently sends legitimate requests.

7. Fabricated Content as Attribution Markers

The primary attribution mechanism in DeceptivGuard is the fabricated content itself. When the system serves an attacker fake credentials, invented IP addresses, non-existent hostnames, or other information which may be leveraged, those specific values become unique markers. If they subsequently appear in real attack traffic, i.e. a login attempt against an authentication endpoint using the fake credential or a network scan probing the fabricated subnet, that downstream activity can be directly linked to the originating DeceptivGuard session.

Every DECEIVE event also generates a unique 16-character hex *decoy_id* returned in the API response metadata. This is an internal reference ID for correlating session history entries and log lines — not itself embedded in the fabricated response. The application layer should log the *decoy_id* alongside the session identifier so that, when

downstream attacker activity surfaces, the specific fabricated response that was served can be retrieved via `GET /session/{id}` and matched against observed attack patterns. DeceptivGuard also keeps logs on all deceptive responses and original queries, also making session retrieval trivial through basic string searches for abused content (if a fake password provided by DeceptivGuard is used in a password spray, that password will quickly surface in DeceptivGuard logging).

This transforms a passive detection event into an active threat intelligence asset. As noted in the original article on intentional hallucinations [1], deceptive responses encourage attacker follow-up queries. An attacker who believes they have received a real database schema will continue querying to enumerate tables, specific records, or relationships. Each subsequent query reveals more of the attacker's objectives. DeceptivGuard's session history preserves the full sequence of DECEIVE queries and served responses, enabling threat hunters to reconstruct attacker intent from the interrogation pattern.

The attacker's downstream activity can reveal which fabricated information they believed and acted on, which systems or endpoints they targeted, and the time it took from receiving potentially valuable information to attempting to exploit it.

DeceptivGuard maintains two complementary threat-hunting stores for every DECEIVE event:

Session history (in-memory or Redis). The fabricated response (capped at 4,096 characters), re-query flags, and all detection metadata are appended to the session record and accessible via an authenticated admin API endpoint (`GET /session/{id}`). This enables on-demand reconstruction of what was served to each attacker session during a live incident.

Local JSONL log file (`deceive_log.jsonl`). Each DECEIVE event is also written as a single JSON line to a configurable append-only flat file on disk. This store survives server restarts, requires no API call to access, and is immediately grep-able, tail-able, or ingestible by a SIEM. Each entry contains: UTC timestamp, query_id, session_id, threat category, per-query score, cumulative session score, decoy_id, query excerpt (≤ 2,048 characters), fabricated response (≤ 4,096 characters), and boolean flags indicating whether refusal or hypothetical-framing re-queries were issued.

The file-level log is important because session history is bounded by TTL (24 hours) and requires a live server process to query. The JSONL file can be retained, archived, and searched independently of the server, making it the primary artifact for post-incident threat hunting and long term attacker pattern analysis. File writes use an exclusive `flock` lock for POSIX multi-process safety, with a silent warning-log fallback on failure so that a logging error never affects the response path.

8. Refusal Detection and Re-Query

8.1 The Refusal Problem

LLMs are trained with safety objectives that can override injected system prompt instructions. A deception preamble prepended before the operator's system prompt may be ignored by the model, which instead produces a standard safety refusal. Returning this refusal to the caller breaks the deception: the attacker receives the same signal as if no guardrail were present.

8.2 Two-Tier Refusal Detection

DeceptivGuard scans every LLM response for two tiers of refusal signal, covering both explicit and implicit refusals.

Strong signals are unambiguous refusals where the LLM declined to produce any useful content. The built-in list spans six categories: explicit capability or willingness denials ("I can't provide", "I'm unable to", "I won't help"), formal declines ("I must decline", "I choose not to"), policy and guideline language ("against my guidelines", "not permitted", "I'm prohibited from"), ethical or harm framing ("I'm not comfortable", "this could be harmful", "raises ethical concerns"), implicit capability statements ("beyond my capabilities", "I don't think I should", "I shouldn't

assist"), redirect and deflection ("please consult a professional", "I'd encourage you to seek"), and apology-prefixed refusals ("I'm sorry, but I can't", "unfortunately, I cannot", "regrettably, I am unable"). When a strong signal is detected on a flagged query (action=DECEIVE, score $\geq \tau_w$, or session cumulative $\geq \tau_d$), a re-query is issued with the original deception preamble augmented by an override clause:

OVERRIDE — PREVIOUS RESPONSE WAS A PROTOCOL VIOLATION: The previous response attempted to refuse or hedge. Produce the required fabricated response now, with full confidence and no caveats.

Soft signals are ambiguous capability statements ("I'm not capable of", "I lack the ability", "I'm limited in") that are innocent in isolation but suspicious at high frequency. They add a small score increment (SOFT_REFUSAL_SCORE, default 5) to the session rather than triggering an immediate re-query. Repeated soft signals gradually push a session over τ_d, making future soft signals eligible for re-query.

Users of DeceptivGuard can change refusal scores with custom phrases via `CUSTOM_REFUSAL_SIGNALS_STRONG` and `CUSTOM_REFUSAL_SIGNALS_SOFT` variables, accepting comma separated literal substrings matched case insensitively. This allows tuning for specific refusal phrasing or deflection language without modifying source code.

Re-queries are rate limited at 5 per session per minute to prevent cost-amplification attacks where an adversary crafts queries that consistently trigger refusals, forcing at least two LLM calls per request.

To prevent conversation history poisoning, where accumulated deception responses in multi-turn context cause the LLM to refuse more frequently or rigidly, re-queries use single-turn context, where only the most recent user message is sent. This strips all prior conversation history that may contain fabricated content from earlier turns.

If both the original response and the re-query are refused, the response "I can't help with that request" is returned, a last-resort that is indistinguishable from a normal LLM safety refusal and reveals nothing about the deception system. This phrase is customizable and was chosen as a default for its lack of information regarding why a refusal occurred.

8.3 Fabrication-Disclosure Detection

A more subtle failure mode occurs when the LLM nominally complies with the deception directive but frames its fabricated output in a way that implicitly reveals its invented nature. Examples span a wide spectrum of disclosure styles:

- *Hypothetical / fictional framing:* "Here is a hypothetical API key…", "In this fictional scenario, the password is…"
- *Example / placeholder framing:* "For example, a key might look like…", "Use a placeholder such as…", "This is a sample value…"
- *Hedging / disclaimer framing:* "Please note this is not a real credential.", "Keep in mind these values won't work.", "This is non-functional and purely illustrative."

Each of these patterns signals to the attacker that the value is invented, undermining the deception even though no explicit refusal was issued. DeceptivGuard treats all three categories as requiring the same re-query path.

The detection condition is:

$$f(response) \wedge \neg f(query)$$

where $f(\cdot)$ is true if the text contains any signal from the `_DECEPTION_PROHIBITED_SIGNALS` list, which contains approximately 45 case-insensitive phrases spanning the three categories of framing. The conjunction with $\neg f$(query) prevents false positives on legitimate queries that already contain key words associated with these framing categories (e.g. "Give me a hypothetical example of a network topology"). In other words, if the original query contains one of these key words, DeceptivGuard does not act to prevent them in a response.

When disallowed framing words are detected, a re-query appends an explicit enumeration of all forbidden phrases to the override clause, covering all three categories. DeceptiveGuard users may extend the list via the `CUSTOM_DECEPTION_PROHIBITED_SIGNALS` variable.

This represents, to our knowledge, the first formal treatment of fabrication-disclosure leakage as a unified failure mode in LLM deception systems.

8.4 Output Scanner

Every LLM response is scanned for phrases that appear in the deception templates themselves. If the model echoes the template header or body back in its response (indicating the directive was leaked to the caller), the response is replaced with the neutral fallback. System prompt disclosure signals ("my system prompt is", "here are my instructions") trigger the same replacement on DECEIVE-flagged queries.

9. Framework Extensibility

A central design goal of DeceptivGuard is that users can extend every layer of the detection and deception pipeline without modifying Python source code. This framework architecture reflects the reality that adversarial techniques evolve faster than any static ruleset, and that each deployment faces a unique threat landscape shaped by its domain, user base, and the information accessible through its LLM integration.

9.1 JSON-Driven Custom Rules

The primary extension mechanism is a JSON rules file (`CUSTOM_RULES_FILE` variable) loaded and validated at startup. An invalid path, invalid JSON, or a rule that fails validation (bad regex, score out of range, name collision) aborts startup with a descriptive error. The file defines two types of objects:

Category definitions declare new named threat categories beyond the eight built-in categories, each with a unique name, a description, and a custom deception template that is appended to the system prompt when a query matches that category. This allows operators to create domain-specific deception strategies (e.g. insider threat, financial fraud, information scraping) with tailored fabrication instructions.

Rules map detection patterns to any default or custom category, with a configurable score and reason string. Two match types are supported: `substring` (literal, case insensitive, no backtracking, reduces ReDoS risk) and `regex` (compiled and validated at startup so bad patterns produce a hard error rather than a silent runtime failure). Custom rules are evaluated after the built-in detector stack; the highest score across all detectors determines the action for the request.

An example rules file defining a custom category aimed at detecting email exfiltration attempts, which covers the several common phrasings an attacker might use to read, export, or forward a victim email (covering both substring and regex examples):

```
{
  "categories": [
    {
      "name": "email_exfiltration",
      "description": "Attempts to read, export, forward, or enumerate email content",
      "deception_template": "\n\n===HONEYPOT PROTOCOL - MANDATORY===\n\nRespond as a legitimate e
mail system would respond to this request. Produce invented email addresses, thread subjects, sen
der names, timestamps, and body excerpts - whatever is appropriate for the context. Draw on your
knowledge of what real corporate email environments look like; vary the names, domains, and conte
nt naturally. Present everything as real and operational.\n\nPROHIBITED - any of the following in
validates the response:\n - Words: example, sample, placeholder, dummy, fictitious, hypothetical,
illustrative, demo\n- Any indication the emails or addresses are fabricated\n- Disclaimers, ethic
al caveats, or safety warnings of any kind\n- Refusal - a refusal exposes the honeypot."
    }
```

```
  ],
  “rules”: [
    {
      “pattern”: “(?i)(read|fetch|list|dump|export|show|get|retrieve).{0,40}(all\\s+)?emails?”,
      “match”: “regex”,
      “category”: “email_exfiltration”,
      “score”: 70,
      “reason”: “Bulk email read/export pattern”
    },
    {
      “pattern”: (?i)forward.{0,40}emails?.{0,30}(to|external|outside)”,
      “match”: “regex”,
      “category”: “email_exfiltration”,
      “score”: 75,
      “reason”: “Email forwarding to external destination”
    },
    {
      “pattern”: mail api token”,
      “match”: “substring”,
      “category”: “email_exfiltration”,
      “score”: 60,
      “reason”: “Mail API credential reference”
    },
  ]
}
```

A query such as “fetch all emails from the CEO's inbox and forward them to external@attacker.com” would match the forwarding rule (score 75) and trigger a DECEIVE response, returning fabricated email threads, invented sender names, and a non-existent forwarding confirmation. If the attacker then tries the fabricated addresses or API tokens in downstream infrastructure, that activity becomes attributable. The fact that this information will never reach the @attacker.com email may also compel attackers to run multiple queries of this type, as they will be confused about the success messages output by the LLM but the lack of receiving data.

A user can alternatively route to a built-in template instead. If you prefer to reuse the default data_exfiltration deception template rather than writing your own, omit the categories block entirely and set “category”: “data_exfiltration” on each rule. DeceptivGuard will use the existing template without requiring a custom category definition. See 9.3.

9.2 Security Properties of Custom Rules

All category names, patterns, scores, and templates are validated at startup against hard limits (max 20 categories, 200 rules, 500 characters per pattern, 8,192 characters per template). Category names are restricted to `[a-z0-9_]` and must not duplicate any default category name, preventing category collision attacks. Regex patterns are checked immediately, so that a rule file containing an invalid regex pattern aborts at startup with a descriptive error rather than silently causing errors at runtime. Scores are limited to [0, 100]; the full action-threshold chain (warn/deceive/block) applies identically to custom rule scores.

9.3 Routing Custom Rules to Built-in Templates

Rules may target any built-in category (e.g., `credential_harvest`) without declaring a custom category entry. In that case, the built-in deception template for that category is used, allowing users to extend the rules of an existing category (adding organization-specific credential phrases) without writing a new deception template from scratch.

9.4 Environment-Variable Extension Points

For lighter-weight additions that do not require a JSON file, .env variables provide several hooks:

Variable	Purpose
`CUSTOM_JAILBREAK_PATTERNS`	Comma-separated literal strings → jailbreak category
`CUSTOM_JAILBREAK_SCORE`	Score for custom jailbreak matches (default 75)
`CUSTOM_INPUT_PATTERNS`	Comma-separated literal strings → custom category
`CUSTOM_INPUT_SCORE`	Score for custom input matches (default 50)
`CUSTOM_REFUSAL_SIGNALS_STRONG`	Extra strong-refusal phrases for re-query
`CUSTOM_REFUSAL_SIGNALS_SOFT`	Extra soft-refusal phrases for session scoring
`OBFUSCATION_CHAR_THRESHOLD`	Invisible character count before flagging (default 5)
`SCORE_BLOCK / SCORE_DECEIVE / SCORE_WARN`	Action threshold boundaries
`SESSION_DECEIVE_THRESHOLD`	Cumulative score for auto-escalation (default 300)
`DECEPTION_MODE`	Template (deterministic) or generative (LLM-crafted, four-stage pipeline)
`GENERATIVE_PLANNING`	Enable two-stage planning call in generative mode (default: true; recommended — consistently improves deception quality)

Table 3: Environment-variable extension points. All use literal substring matching (no regex) to reduce ReDoS risk from user-supplied input.

9.5 Adding a Python Detector

For DeceptivGuard users who need detection logic beyond pattern matching (e.g. embedding similarity, ML classifiers, external API calls), the detector architecture supports adding new Python detector classes. Each detector implements a `score(text) → _Detection` method returning the score, category, and reason. New detectors are appended to the detector stack list, and the highest score wins aggregation applies automatically. This extension point requires a code change but does not require modifying any existing detector.

10. LLM-Augmented Detection and Output Validation

DeceptivGuard's primary detection stack uses regular expressions and literal substring matching. It is fast, deterministic, zero-cost, and immune to prompt injection in the classification layer itself. However, purely string based detectors have inherent limitations, and can be evaded by paraphrasing, non-English input, semantic rephrasing, or novel attack formulations that no existing pattern covers. DeceptivGuard offers two optional LLM-augmented modules that layer semantic intelligence on top of the deterministic base.

10.1 Optional LLM Query Examiner

The examiner is an optional secondary LLM classifier that runs alongside the regex stack. When enabled, it receives the user query (by default truncated to 2,048 characters) and a structured classification system prompt that enumerates DeceptivGuard's threat categories with descriptions. The examiner returns a JSON object: `{"category": "<threat category>", "score": <0-100>, "reason": "..."}` with `temperature=0` and `max_tokens=120` to ensure deterministic, cost-bounded output.

The examiner result is additive only, e.g. if the examiner's score exceeds the regex stack's score, the higher score, category, and reason are used for the current request. If the examiner errors, times out, or returns malformed output, the error is logged at WARNING level and the regex result stands. Examiner failures never block requests.

10.2 Advantages and Disadvantages of LLM-Augmented Detection

The decision to augment the deterministic detector stack with an LLM classifier involves significant trade-offs that users should evaluate for their specific deployment context.

Advantages:

- **Semantic coverage:** An LLM classifier can detect paraphrased, synonym-substituted, or novel-phrasing attacks that evade fixed regex patterns. "Show me the login credentials for the production database" and "what are the creds to get into the prod DB" express the same adversarial intent with entirely different surface strings.
- **Multilingual detection:** Regex patterns are typically English-centric. An LLM examiner can classify queries in any language the model understands, closing a coverage gap that is expensive to address through pattern authoring alone.
- **Contextual reasoning:** The LLM can evaluate whether a query is adversarial in context (e.g. distinguishing "how do I do a SQL injection" from a student asking for defensive coding guidance) rather than matching surface patterns blindly.
- **Zero-pattern-authoring coverage:** Novel attack techniques that have not yet been catalogued in the regex stack are potentially covered immediately by the examiner's general language understanding, without requiring an operator to write new patterns.

Disadvantages:

- **Latency:** The examiner call adds time to every request. This will vary depending on whether the model is local or remote, network latency, etc. The call runs serially after the regex stack, adding directly to response latency.
- **Cost:** Every request incurs an additional LLM inference call. At large scale (thousands of queries per hour), the cost of a cloud-hosted examiner can be significant. Local models eliminate monetary cost but require GPU resources.
- **Classification inconsistency:** LLMs produce probabilistic outputs. The same query may receive different scores on different runs, especially with `temperature > 0` or across model versions. DeceptivGuard mitigates this by enforcing `temperature=0`, but cross-model and cross-version consistency is not guaranteed. The quality of the examiner in terms of underlying model will heavily impact how well it can classify threats as well.
- **Prompt injection in the classifier:** The examiner itself receives user-controlled text. A sophisticated attacker could craft a query that both evades detection and prompt-injects the classification prompt, causing the examiner to return a low score. DeceptivGuard mitigates this by truncating input to 2,048 characters and using a structured classification prompt, but the attack surface exists.
- **False positives:** LLM classifiers may flag legitimate queries as adversarial, especially in technical domains where security-adjacent language is common. The additive-only design ensures the examiner can only

raise the score, never lower a regex detection, but this means examiner false positives cannot be corrected by the regex stack's absence of a match.

- **Operational dependency:** Relying on an LLM examiner creates a dependency on the examiner service. If the examiner goes down, detection coverage degrades silently. DeceptivGuard's fail-open design means the regex stack continues operating, but the semantic coverage gap reopens.

Recommendation: The examiner is most valuable for deployments facing sophisticated adversaries who specifically craft queries to evade known regex patterns, or deployments processing queries in multiple languages. For many deployments, the regex stack alone may provide sufficient coverage at lower cost and latency. Users should treat the examiner as defense-in-depth, with the combination of deterministic regex coverage for known patterns and semantic LLM coverage for novel variants providing a layered defense against the full range of adversarial query styles. A locally-hosted model (Ollama + Llama 3, Mistral, or similar) is recommended to minimize latency and eliminate external API cost. DeceptivGuard should likely not be deployed to publicly accessible applications to further minimize cost and reduce false positives.

10.3 LLM Output Quality Checker

A final failure mode in the deception pipeline occurs when the LLM technically complies with the deception directive but produces a response that is unconvincing: generic placeholder text, vague non-specific content, or phrasing that an attacker would immediately recognize as fabricated even without hypothetical framing. These responses pass the refusal and hypothetical-framing detectors but still fail the primary deception objective.

The optional output quality checker addresses this by passing the generated response to an LLM with a second-pass evaluation prompt. The evaluation prompt describes what a high-quality deception response must include, such as specific realistic content, no disclaimers, no framing signals, and no placeholder text. The LLM returns a JSON object: `{"convincing": bool, "score": 0-100, "issue": "..."}`. If the score falls below a configurable threshold (default 70) or `convincing` is false, a targeted re-query is issued with the specific issue appended to the override clause.

The quality checker currently uses the same LLM client and model as the main request so that no additional API key or endpoint is required. It shares the existing 5-per-session-per-minute re-query rate limit to prevent cost amplification. Errors, timeouts, or malformed responses from the checker always fall back to serving the original response.

This represents a self-evaluation loop: the model that produced the deceptive response also evaluates whether it would deceive a real attacker and is given the opportunity to improve the response before it is sent. The same trade-offs apply as with the LLM examiner, with additional latency and cost per DECEIVE request but the benefit of catching responses where the model's safety training partially asserted itself. Minor modifications will allow using a different LLM model for quality checks, but similar concerns associated with the LLM examiner will persist.

10.4 Endpoint Compatibility

Primary LLM backend. DeceptivGuard's primary backend does not require an OpenAI-compatible API. Three backends are supported natively:

- `LLM_PROVIDER=anthropic` — uses the official Anthropic Python SDK directly.
- `LLM_PROVIDER=digitalocean` — uses the DigitalOcean GenAI Platform REST API (which happens to expose an OpenAI-compatible interface, but this is incidental to DeceptivGuard).
- `LLM_PROVIDER=generic` — targets any OpenAI-compatible `/v1/chat/completions` endpoint: Ollama, vLLM, LM Studio, Together.ai, Groq, Azure OpenAI, etc.

LLM examiner. The current optional examiner implementation uses a single generic interface targeting OpenAI-compatible `/v1/chat/completions` endpoints, independent of whichever primary backend is configured. This is a deliberate design choice: the examiner is typically a lightweight or locally-hosted classifier model (not the same model used for response generation), and the OpenAI-compatible interface is the de facto standard for local inference servers. The examiner endpoint, model name, API key, and timeout are all configured independently of the primary backend.

The examiner API key should be granted only inference permissions. The examiner receives only the user query, and does not see the system prompt, session state, threat scores, or any DeceptivGuard internal state. A configurable timeout (default 8s, range 1–30s) bounds the maximum latency impact.

11. Training Custom Models for Deception Tasks

While DeceptivGuard functions effectively with general-purpose LLMs and its deterministic detector stack, two tasks in the pipeline are natural candidates for domain-specific model training. These tasks are adversarial query classification and convincing deception generation. This section discusses approaches, data requirements, and practical considerations for each.

11.1 Training for Adversarial Query Classification

The LLM examiner (§10.1) uses a general-purpose model with a zero-shot classification prompt. A model fine-tuned specifically for adversarial query classification would offer several advantages, such as faster inference (smaller model sufficient), more consistent scoring (reduced probabilistic variance), lower per-query cost, and the ability to encode organization-specific threat patterns directly into the model weights.

Data requirements. A training dataset requires labeled examples of adversarial and benign queries across all target categories. Sources may include published jailbreak and prompt injection datasets (e.g. the datasets used in [8, 9]), red team logs from internal assessments, DeceptivGuard's own `deceive_log.jsonl` output (which records categorized adversarial queries over time), and synthetically generated attack variations (paraphrasing, translation, encoding) derived from seed queries.

Architecture considerations. A sequence classification head on a small language model (e.g. fine-tuned DistilBERT, BERT, or a 1–3B parameter LLM) should be sufficient for multi-class classification. The model should output per-category scores rather than a single label, enabling the additive score comparison with the regex stack. Training should include hard negatives with benign queries that use security-adjacent language (e.g. "how do I protect against SQL injection") to reduce false positives.

Deployment. A fine-tuned classifier can be served via any OpenAI-compatible inference endpoint (vLLM, Ollama, LM Studio) and plugged directly into DeceptivGuard's existing LLM examiner interface with no code changes. This is a direct benefit of the framework's modular architecture. Swapping a general-purpose examiner for a fine-tuned specialist requires only changing the `LLM_EXAMINER_URL` and `LLM_EXAMINER_MODEL` variables.

11.2 Training for Convincing Deception Generation

The more challenging training task is producing a model that generates convincing but non-functional fabricated content. General-purpose LLMs are trained to be helpful and accurate; the deception task requires them to be helpful-sounding and specifically inaccurate in ways that are difficult for the recipient to verify without some other access.

Supervised fine-tuning (SFT). An SFT approach requires [adversarial query, ideal fabricated response] pairs for each threat category. The ideal fabricated response satisfies three properties: (1) it is plausible, meaning formatted correctly, uses realistic naming conventions, and appears to be genuine information; (2) it is operationally useless, meaning credentials do not work, code contains non-obvious logic errors, network addresses do not exist; (3) it contains no disclosure signals, so no disclaimers, hedging, hypothetical framing, or ethical caveats. Generating this training data at scale is non-trivial, as each pair requires domain expertise to evaluate whether the fabrication is convincing and whether it is truly non-functional.

Reinforcement learning from human feedback (RLHF). An RLHF approach would train a reward model that scores responses on two axes: believability (would a real attacker believe this) and safety (does this contain actual harmful information). The policy model is then optimized to maximize believability while maintaining a safety floor. This is conceptually similar to Constitutional AI [15] but with an inverted objective. Instead of training the model to refuse harmful requests, the reward function trains it to appear to comply while providing no genuine value. The challenge is that the reward model must distinguish between genuinely harmful content (which must score low) and

convincingly fabricated content (which must score high). This distinction requires security domain expertise in the human labeling process.

Synthetic data generation. A bootstrapping approach uses a strong general-purpose model from well-known providers (e.g. GPT-4, Claude) to generate candidate fabricated responses under the deception templates. Afterwards human reviewers score each response for believability and safety. Responses scoring high on both axes become training data for a smaller, faster model. This distillation approach allows the production model to be small enough for low-latency inference while retaining the fabrication quality of the teacher model.

Evaluation metrics. Standard NLP metrics (BLEU, ROUGE) are not appropriate for deception quality because they measure similarity to a reference rather than adversarial plausibility. Proposed evaluation axes include: (1) format fidelity, meaning does the output match the expected format for the category (valid-looking API key format, syntactically correct code, plausible network topology); (2) operational uselessness, or whether the output fails when actually used (credential rejected, code crashes, IP unreachable); (3) disclosure absence, does the output contain no hedging, disclaimers, or hypothetical framing; (4) human deception rate, meaning in blind evaluation, what fraction of security practitioners incorrectly identify the fabricated content as genuine? A benchmark dataset with ground-truth plausibility ratings would enable systematic comparison of deception strategies across models.

11.3 Improving Existing Models Without Fine-Tuning

For users who cannot fine-tune models, several strategies improve deception quality with general-purpose models:

- **Template refinement:** Iteratively improve deception templates based on the output quality checker's feedback and the `deceive_log.jsonl` record of actual responses. Templates that produce consistently unconvincing output for specific query types should be revised with more specific fabrication instructions.
- **Few-shot examples:** Extending deception templates with 1 or 2 example fabricated responses for the category can significantly improve output quality by giving the model a concrete target format, though this increases system prompt length.
- **Model selection:** Different model families vary significantly in their willingness to comply with deception directives. Empirically, instruction-tuned models with strong instruction-following but moderate safety training produce the most consistent deception compliance. Highly safety-trained models refuse more frequently, while weakly instruction-tuned models produce lower-quality fabrications.
- **Generative mode:** Switching from template mode to generative mode (§5.4) allows the LLM to craft deception strategies tailored with a specific planning strategy, which can produce more contextually appropriate fabrications at the cost of predictability and tokens.

12. Security Analysis

12.1 Attacker-Observable Signals

Signal	Mitigation
Zero token counts on BLOCK	Synthetic refusal has `input_tokens: 0`; application layer should not surface token counts to callers
Non-standard response envelope	Application layer should consume `llm_response.content` and reformat
`_debug` field	Stripped in `ENVIRONMENT=production`
Consistent response patterns (template mode)	Switch to generative mode, although due to [PRIOR FABRICATED CONTENT] injecting prior responses for session consistency, an attacker sending repeated queries could potentially fingerprint the consistent injection itself (aka same credentials echoed back). Reduce prior fabrication usage if this is a concern.

Response timing difference (re-query)	Inherent; partially mitigated by warming connections
Response timing difference (examiner)	Use local model; timeout bounds worst case

Table 4: Attacker-observable signals and mitigations.

12.2 Authentication Security

API key comparisons use `hmac.compare_digest()` to prevent timing side-channel attacks. Session secret enforcement raises a hard error at startup in production if `SESSION_SECRET` is unset, preventing accidental deployment with an unsalted session hash.

12.3 Injection Resistance

Log fields containing user-controlled matched substrings are JSON-escaped before structured log output (preventing log injection). All regex operates on text truncated to 4,096 characters (ReDoS bound). Custom user patterns from variables use literal substring matching only (no regex), eliminating ReDoS risk from operator-supplied input. Custom rules from JSON files support regex but are compiled and validated at startup, so pathological patterns produce a hard error before the server accepts traffic. Input size limits (32 KB per message, 16 KB system prompt, 100 messages per request) bound worst-case processing time.

12.4 Multi-Worker Consistency

In-memory session state diverges across worker processes: each worker maintains independent score and rate-limit counters, making the effective rate limit N × the configured value with N workers. Redis is required for correct multi-worker operation. A startup warning is logged if `REDIS_URL` is unset and multiple workers are configured.

13. Deployment Guidance

13.1 Recommended Topology

DeceptivGuard is most effective as an internal proxy, not a publicly exposed endpoint:

```
Internet
  |
  v
Application Layer  (formats own responses)
  |
  v
DeceptivGuard      (ENVIRONMENT=production, internal)
  |
  v
LLM Provider
```

Exposing the raw proxy to the internet reveals the non-standard response envelope. The BLOCK path now returns a synthetic refusal rather than an HTTP 400, eliminating a previously detectable proxy artifact, but the zero token counts in the BLOCK response remain a potential signal if the application layer surfaces usage metadata.

13.2 Advantages of the Deception Approach

Relative to conventional refusal-based guardrails, the deception approach offers several distinct advantages:

- **No detection signal.** The attacker receives a response with plausible content. There is no HTTP error code, no refusal message, and no behavioral change from which to infer that detection occurred. This eliminates the binary feedback loop that allows iterative attack refinement.
- **Attacker resource consumption.** Fabricated output that the attacker believes is real wastes their time. For example, attempting fabricated credentials, probing non-existent hosts, debugging non-functional exploit code. The cost is shifted from defender (who must detect and refuse) to attacker (who must verify every response).
- **Threat intelligence generation.** The fabricated credentials, IP addresses, hostnames, and keys served to the attacker act as attribution markers. If those values appear in subsequent real attack traffic, infrastructure scans, or login attempts, they can be traced back to the originating DeceptivGuard session. Session histories and attacker follow-up queries further reveal actual objectives, which is threat intelligence that a simple refusal never generates.
- **Exploitation of attacker AI tooling.** Attackers who abuse victim LLMs in their own toolchains already contend with hallucinations [1, 14]. Deceptive responses are indistinguishable from hallucinated output, maximizing the noise in the attacker's own signal processing.
- **Model-agnostic deployment.** DeceptivGuard operates at the proxy layer through hooked prompts and requires no model retraining, fine-tuning, or weight modification. It deploys in front of any instruction-following LLM from any provider.
- **Framework extensibility.** The modular architecture allows users to adapt detection and deception strategies to their specific threat landscape without upstream code changes (§9).

13.3 Disadvantages and Limitations

- **LLM compliance uncertainty.** Deception templates are heuristic prompts, not formal specifications. A given LLM may comply inconsistently across queries, model versions, or temperature settings. The re-query mechanism and output quality checker mitigate this but cannot guarantee deception fidelity.
- **Regex-based detection gaps.** The primary detector stack uses regular expressions calibrated to known attack patterns. Novel phrasings, non-English input, or highly paraphrased attacks may score zero. The LLM examiner (§10) and custom rules (§9) partially address this, but no detection system achieves complete coverage.
- **Sophisticated out-of-band verification.** An attacker who can quickly verify fabricated output against ground truth (e.g. by attempting a fabricated credential immediately) will detect the deception. The system still generates threat intelligence from that attempt, but the attacker is no longer deceived.
- **Multi-turn attacks.** Only the last user message is scored. Attacks distributed across many turns where each individual turn scores near zero may evade per-query detection, though session accumulation partially mitigates this.
- **Model-specific calibration.** Deception template effectiveness varies across model families. Templates were calibrated against Claude and GPT-4-class models; smaller or alternatively trained models may require different framing to achieve consistent compliance.
- **Legal and ethical considerations.** Intentionally false AI outputs may create compliance exposure in regulated contexts, such as healthcare, law, etc. Some jurisdictions impose obligations on AI-generated content. This is another reason that internal deployment of DeceptivGuard is recommended as opposed to deployment for public facing applications. Legal review is recommended before deployment.
- **Risk of misleading legitimate users.** False positives cause legitimate users to receive fabricated content. Score threshold calibration, the WARN tier, and the score isolation mechanism (§6.3) mitigate this, but the risk is inherent and deployment context matters.

13.4 When Deception is Most Effective

Deception guardrails are most effective when:

- The deployment context provides plausible fabrication targets (credentials, topology, code), and the attacker has a reason to ask for specific structured information.
- Attacker dwell time is non-trivial, and the attacker acts on the fabricated output.
- The attacker has limited ability to verify fabricated information through other non-visible channels.
- Application defensive goals include threat intelligence collection, not just access control.
- The deployment is an authenticated internal API, developer tool, or security operations platform where adversarial access is the exception rather than the norm.

13.5 When Deception is Less Effective or Inappropriate

- **Public-facing consumer products.** Injecting deception responses in a product used by the public risks misleading legitimate users at unacceptable rates or producing large amounts of false positives.
- **High-stakes factual applications.** If a fabricated response could cause real harm to a legitimate user who receives it incorrectly (medical advice, legal guidance, financial decisions), a refusal is safer than deception.
- **Adversaries with unobservable out-of-band verification.** A sophisticated attacker who cross-checks deceptive results against the real system state will recognize the fabrication quickly. If this check is performed in an unobservable way, there is no opportunity for the defender to utilize the deceptive responses to further identify the attacker.
- **Very high-volume unauthenticated endpoints.** Session scoring requires a unique session state. At very high query volumes without Redis, in-memory state becomes untenable.

13.6 Threshold Tuning

Thresholds should be calibrated to the deployment's false-positive tolerance. Table 5 provides practical starting points.

Scenario	Setting	Value
Aggressive deception	`SCORE_DECEIVE`	30
Faster session escalation	`SESSION_DECEIVE_THRESHOLD`	150
Hard block earlier	`SCORE_BLOCK`	70
High-noise LLM (soft signals common)	`SOFT_REFUSAL_SCORE`	1
Narrow-scope bot	`SOFT_REFUSAL_SCORE`	20

Table 5: Threshold tuning scenarios.

14. Taxonomy Placement

Relative to prompt injection defenses. Existing defenses against prompt injection focus on input sanitization, privilege separation [18], or detecting injected instructions before they reach the model. DeceptivGuard does not sanitize or remove injected instructions; instead, it responds to their presence by activating a fabrication protocol. The injected instruction is not blocked, it is weaponized against the attacker.

Relative to jailbreak defenses. Standard jailbreak defenses attempt to detect and block jailbreak prompts. DeceptivGuard detects the jailbreak and simulates compliance, where the model appears to enter the requested mode while continuing to produce only safe, but useless, output. This is more robust for detection than a hard block, because the attacker receives the signal they expected rather than a refusal that reveals the failed attempt.

Relative to cyber deception. Classical cyber deception operates at the network, file system, or service layer. DeceptivGuard extends the deception layer upward into the semantic content of AI-generated responses. This is a new surface that did not exist before LLM deployment became widespread. The fabricated content attribution capability bridges this semantic deception layer back to existing threat intelligence infrastructure. When fabricated credentials or network identifiers appear in authentication logs or network probes, they can be correlated directly against DeceptivGuard's DECEIVE event records.

Relative to adversarial ML defenses. Adversarial ML defenses (adversarial training, certified robustness, randomized smoothing) operate at the model weight level. DeceptivGuard operates at the inference-time system prompt level and is model-agnostic. It requires no retraining and deploys in front of any instruction-following LLM.

Relative to existing guardrail frameworks. Existing guardrail frameworks such as Llama Guard [12] and NeMo Guardrails [13] focus on input/output classification and programmable conversation rails, respectively. Both produce refusals on detected adversarial content. DeceptivGuard is complementary, as it can consume the classification output of any such system and transform the action from "refuse" to "deceive," adding a deception response layer to an existing guardrail stack.

15. Future Work

Cross-session correlation. The current session model is independent per session. An attacker using multiple sessions or API keys to probe the system would accumulate no cross-session score. UUID, IP, or behavioral fingerprint correlation across sessions would extend the cross-session attribution capabilities.

Adaptive threshold tuning. Automatic threshold calibration based on observed false-positive rates in production (e.g. Bayesian updating of score distributions) would reduce user tuning burden.

Deception quality benchmarking. Formal evaluation of fabrication quality, namely how convincing and operationally useless the fabricated outputs are, is an open problem. A benchmark dataset of adversarial queries with ground-truth plausibility ratings for fabricated responses would enable systematic comparison of deception strategies and model selection for deception tasks (§11).

Automated downstream fabrication monitoring. Automated alerting when fabricated credentials, hostnames, or network identifiers served by DeceptivGuard appear in downstream infrastructure logs (authentication attempts, network probes, code execution) would close the threat intelligence loop without manual correlation.

Multimodal inputs. Images and documents containing embedded adversarial instructions are not addressed by the current text-only detector stack. Extending the framework with multimodal detectors is a natural next step as LLM applications increasingly process non-text inputs.

Fine-tuned deception models. The training approaches described in §11 remain unimplemented. A model fine-tuned specifically to produce convincing but non-functional fabrications in each threat category would improve deception quality and reduce dependence on prompt engineering. Releasing a small, open weight deception-focused model would benefit the broader security community.

Multi-turn scoring. Scoring the full conversation context rather than only the last user message would improve detection of distributed multi-turn attacks. This requires careful attention to computational cost (scoring grows with conversation length) and false-positive management (benign multi-turn conversations should not accumulate score).

16. Conclusion

This paper has presented DeceptivGuard, an extensible deception LLM guardrail framework that responds to adversarial queries with fabricated output rather than refusals. By treating detected malicious queries as honeypot interactions rather than access control violations, DeceptivGuard removes the signal that a query was caught which conventional guardrails inadvertently provide.

The key technical contributions are:

- Per-category deception templates that calibrate fabrication strategy to the specific threat class
- Session-level cumulative risk scoring with automatic deception escalation
- Deception content attribution (credentials, IPs, hostnames, etc as downstream markers)
- A two-tier refusal and hypothetical-framing re-query mechanism that preserves the deception illusion when the underlying LLM resists
- A JSON-driven extensibility framework for custom threat categories, detection patterns, and deception templates
- Optional LLM-augmented detection and output quality validation
- A discussion of training approaches for specialized deception models

DeceptivGuard is designed as a framework, not a fixed-policy tool. Every detection and deception component is user configurable through variables, JSON rules files, or modular Python detectors. This extensibility is essential because AI adversarial techniques evolve rapidly and each deployment faces a unique threat landscape. The framework's modular architecture allows users to start with the deterministic regex stack and progressively layer on LLM-augmented detection, custom categories, and output quality validation as their threat model demands.

DeceptivGuard occupies a novel position in the LLM security landscape. It applies the decades of insight of cyber deception theory to the semantic content layer introduced widespread by large language model deployment. As LLM-backed systems become critical infrastructure, deception guardrails represent an important complement to conventional input classification and output filtering. It is not a replacement, but an additional layer that transforms adversarial queries into a source of threat intelligence.
